(Received

Stationary inverted H Balmer and Lyman populations were observed from a low pressure water-vapor microwave discharge plasma. The ionization and population of excited atomic hydrogen levels was attributed to energy provided by a catalytic resonance energy transfer between hydrogen atoms and molecular oxygen formed in the water plasma. The catalysis mechanism was supported by the observation of O^{2+} and H Balmer line broadening of 55 eV compared to 1 eV for hydrogen alone. The high hydrogen atom temperature with a relatively low electron temperature, $T_e = 2 \text{ eV}$, exhibited characteristics of cold recombining plasmas. These conditions of a water plasma favored an inverted population in the lower levels. Thus, the catalysis of atomic hydrogen may pump a cw HI laser. From our results, laser oscillations are expected from (i) $n = 3, n = 4, n = 5, n = 6, n = 7$ and $n = 8$ to $n = 2$, (ii) $n = 4, n = 5, n = 6$, and $n = 7$ to $n = 3$ and (iii) $n = 5$ and $n = 6$ to $n = 4$. Lines of the Balmer series of $n = 5$, and $n = 6$ to $n = 2$ and the Paschen series of $n = 5$ to $n = 3$ were of particular importance because of the potential to design blue and 1.3 micron infrared lasers, respectively, which are ideal for many communications and microelectronics applications. High power hydrogen gas lasers are anticipated at wavelengths, over a broad spectral range from far infrared to violet which may be miniaturized to micron dimensions. Such a hydrogen laser represents the first new atomic gas laser in over a decade, and it may prove to be the most versatile and useful of all.

1. INTRODUCTION

For the last fifteen years there has been an aggressive search for a blue laser. A blue laser would significantly improve the performance of many applications and open new venues. Blue lasers that are durable and bright have significant applications such as superior displays, optical sensors, laser printers and scanners, fiber optical and undersea optical communications, satellite and undersea detection and targeting of submarines, undersea mine detection, undersea salvage, medical devices, and higher density compact disk (CD) players. The shorter (blue) wavelength could be more sharply focused such that the capacity of magnetic and optical storage may be increased. Digital versatile disks (DVDs) which rely on red aluminum indium gallium phosphide (AlInGaP) semiconductor lasers have a data capacity of about 4.7 gigabytes (Gbytes) compared to 0.65 for compact discs. The capacity could be increased to 15 Gbytes with a suitable violet laser. Despite the tremendous value of a blue laser, advancements have been limited due to a lack of materials which emit blue light or blue-emitting plasmas capable of lasing.

Recombination of injected electrons and holes in InGaN has been extensively pursued as a suitable blue laser [1]. Unfortunately, after over a decade of effort with an estimated expenditure of \$1 B, blue diode lasers are still plagued by inadequate substrates, crystal layer dislocations, and defects that increase over time with the requisite high drive currents. Frustration over these and other impediments to commercialization of this important device has given rise to the view that commercial success may depend on the discovery of something completely new [2].

Inverted Lyman and Balmer populations may permit a continuous wave (cw) laser at blue wavelengths. For the last four decades, scientists from academia and industry have been searching for lasers using hydrogen plasma [3–6]. Developed sources that provide a usefully

intense hydrogen plasma are high powered lasers, arcs and high voltage DC and RF discharges, synchrotron devices, inductively coupled plasma generators, and magnetically confined plasmas. However, the generation of population inversion is very difficult. Recombining expanding plasma jets formed by methods such as arcs or pulsed discharges is considered one of the most promising methods of realizing an H I laser.

Because the population of hydrogen states is overwhelmingly dominated by the ground state even in the most intense plasmas, the realization of an H I laser requires an overpopulation in a state with $n_i > 2$ which decays to a state with $1 < n < n_i$. Thus, an H I laser based on a Balmer transition is feasible for a mechanism which produces an overpopulation in a corresponding state. The Balmer α , β , γ , and δ lines of atomic hydrogen at 6562.8 Å, 4861.3 Å, 4340.5 Å, 4101.7 Å in the visible region are due to the transitions from $n = 3$, $n = 4$, $n = 5$, and $n = 6$ to $n = 2$, respectively. An H overpopulation of $n > 3$ that is above threshold could be the basis of a blue laser. But, lasing of a blue Balmer line has been difficult to achieve even with cold recombining plasmas. Akatsuka and Suzuki [6], for example, were able to achieve an overpopulation for level pairs 4-3 and 5-4 only for a recombining plasma generated in a arc-heated magnetically trapped expanding plasma jet [6].

Rather than using recombining arcs or recombining electron-hole pairs in semiconductors to achieve lasing at blue wavelengths, a chemical approach was pursued. It was previously reported that a new chemically generated plasma source has been developed that operates by incandescently heating a hydrogen dissociator and a catalyst to provide atomic hydrogen and gaseous catalyst, respectively, which react to produce an energetic plasma called a resonance transfer (rt)-plasma [7-8]. Intense VUV emission was observed at low temperatures (e.g. $\approx 10^3$ K) and an extraordinary low field strength of about 1–2 V/cm from atomic hydrogen and

certain atomized elements or certain gaseous ions which singly or multiply ionize at integer multiples of the potential energy of atomic hydrogen, $E_h = 27.2 \text{ eV}$ where E_h is one hartree.

The theory has been given previously [9–10].

The ionization of Rb^+ and an electron transfer between two K^+ ions (K^+ / K^+) provide a reaction with a net enthalpy of E_h . The presence of each of these gaseous reactants formed an rf-plasma with atomic hydrogen having strong vacuum ultraviolet (VUV) emission. Remarkably, a stationary inverted Lyman population was also observed, and a collisional radiative model was used to determine that the observed overpopulation was above threshold for $n = 3$ demonstrating that these catalytic reactions may pump a red cw HI laser [11].

For oxygen, there are several chemical reactions that fulfill the catalyst criterion—a chemical or physical process with an enthalpy change equal to an integer multiple of E_h . The bond energy of the oxygen molecule is 5.165 eV, and the first, second, and third ionization energies of an oxygen atom are 13.61806 eV, 35.11730 eV, and 54.9355 eV, respectively [12]. The reactions $\text{O}_2 \rightarrow \text{O} + \text{O}^{2+}$, $\text{O}_2 \rightarrow \text{O} + \text{O}^{3+}$, and $2\text{O} \rightarrow 2\text{O}^+$ provide a net enthalpy of about 2, 4, and 1 times E_h , respectively [12]. Lasing directly from oxygen is unknown, but lasing from inverted water vibration-rotational levels in water plasmas which may be from hydrogen-oxygen mixtures has been achieved several decades earlier [13]. In addition, helium-water plasmas as well as water plasma lasers were explored for a source of submillimeter wavelengths [14]. More recently, emission from OH^+ radicals in water and helium-hydrogen water plasmas has been investigated as an efficient source of radiation in the region $\lambda < 2000 \text{ \AA}$ for the replacement of expensive working media based on krypton and xenon in microelectronics, photochemistry, and medical applications [15]. These prior water-plasma light sources were based on high-voltage glow discharges.

In our experiments, microwave water plasmas were used as sources of O_2 and atomic hydrogen. The energetic hydrogen atom densities and energies were calculated from the width of the 6563 Å Balmer α line emitted from a control hydrogen and water microwave plasmas. The characteristic emission from the oxygen catalyst was measured. The absolute hydrogen excited state level densities, reduced population densities, and overpopulation densities for lasing were determined from intensity-calibrated high resolution visible spectra in the region 4000 to 7000 Å and VUV spectra in the region 900-1300 Å. Remarkably, stationary inverted Balmer and Lyman populations were observed, and to our knowledge, this is the first report of population inversion in a water plasma. The parameters of a water-plasma laser of Balmer, Paschen, and Brackett series line emission were determined using the spectrally determined reduced population densities. The plasma was further characterized by measuring the electron temperature T_e and density using a Langmuir probe.

II. EXPERIMENTAL

The VUV spectrum (900 – 1300 Å), the width of the 6562.8 Å Balmer α line, and the high resolution visible spectra (4000 – 7000 Å) were recorded on light emitted from microwave, capacitively coupled RF, inductively coupled RF, and glow discharge water plasmas performed according to methods and setups reported previously [8–10, 16–8]. Hydrogen and hydrogen (10%) mixed with xenon, krypton, or nitrogen control plasmas were run under matching conditions. The microwave experimental set up shown in Fig. 1 comprised a quartz tube cell, a source of water vapor or ultrapure hydrogen, a flow system, and a visible spectrometer or a VUV spectrometer that was differentially pumped. Water vapor was formed in a heated insulated reservoir and flowed through the half inch diameter quartz tube at a flow rate of 10 standard

$\text{cm}^3 \cdot \text{s}^{-1}$ (sccm) at a corresponding pressure of 50–100 mTorr. At this pressure, room temperature was sufficient for maintaining the water vapor. The tube was fitted with an Evenson coaxial microwave cavity (Ophos) having an E-mode [19-20]. The input power to the plasma at 2.45 GHz by an Ophos model MPG-4M generator was set at 50 W and 90 W as described previously [9, 10, 16–18]. Hydrogen control plasma were run under matching conditions. Each gas flow was controlled by a 0-20 sccm range mass flow controller (MKS 1179A21CS1BB) with a readout (MKS type 246). The cell pressure was monitored by a 0-10 Torr MKS Baratron absolute pressure gauge.

In addition, the effect of addition of oxygen or hydrogen to the intensities of the Balmer lines recorded on the water plasma was determined. Using the mass flow controller, 0, 2, 5, 10, and 20 volume % ultrapure gas was mixed with the water vapor while maintaining a constant flow rate and pressure, and each corresponding high resolution visible spectrum (4000 – 7000 Å) was recorded.

High resolution visible spectra (4000 – 7000 Å) were recorded on light emitted from hydrogen and water hollow cathode glow discharge plasmas performed according to methods reported previously [16, 18]. The glow discharge cell that comprised a five-way stainless steel cross that served as the anode with a hollow stainless steel cathode. The plasma was generated at the hollow cathode inside the discharge cell. The hollow cathode was constructed of a stainless steel rod inserted into a steel tube, and this assembly was inserted into an Alumina tube. A flange opposite the end of the hollow cathode connected the spectrometer with the cell. It had a small hole that permitted radiation to pass to the spectrometer. An DC power supply ($U = 0 - 1$ kV, $I = 0 - 100$ mA) was connected to the hollow cathode to generate a discharge. The DC voltage and current were 300 V and 300 mA, respectively, corresponding to 90 W. A Swagelok adapter at the very end of the steel cross provided a gas inlet and a connection with the pumping

system, and the cell was pumped with a mechanical pump. Valves were between the cell and the mechanical pump, the cell and the monochromator, and the monochromator and its turbo pump. The five-way cross was pressurized with 50–100 mTorr of gas which was maintained with a gas glow rate of 10 sccm.

High resolution visible spectra (4000–7000 Å) were recorded on light emitted from hydrogen and water capacitively coupled RF discharges plasmas performed according to methods reported previously [16]. The experimental set up comprised a Pyrex cell reactor (38 cm in length and 13 cm ID) with a diode configuration in which the plasma was confined between two parallel circular stainless steel electrodes (0.1 mm thick × 7.6 cm diameter with a 2 cm separation). For spectroscopic measurements on the plasma emission, a 1 cm diameter quartz window was located in the Pyrex cell wall at the center of the gap between the electrodes. At each end of the cell, a Pyrex cap sealed to the cell with a Viton O ring and a C-clamp. One cap incorporated ports for gas inlet and cathode feedthrough. The other cap incorporated ports for gas outlet and anode feedthrough. The cathode was connected to an 13.56 MHz RF generator (RF VII, Inc., Model MN 500) with a matching network (RF Power Products, Inc., Model RF 5S, 300 W). The input power was 90 W, and the reflected power was less than 1 W. The gas flow rate and pressure were 10 sccm and 50–100 mTorr, respectively.

High resolution visible spectra (4000-7000 Å) were recorded on light emitted from hydrogen and water inductively coupled RF discharges plasmas performed according to methods reported previously [16]. A quartz cell which was 500 mm in length and 50 mm in diameter served as the plasma reactor. A Pyrex cap sealed to the quartz cell with a Viton O ring and a C-clamp incorporated ports for gas inlet, outlet, and photon detection. An unterminated, nine-turn, 17 cm long helical coil (18 gauge magnet wire) wrapped around the outside of the cell was connected to an 13.56 MHz RF generator (RF VII, Inc., Model MN 500) with a matching

network (RF Power Products, Inc., Model RF 5S, 300 W). The coil inductance and resistance were $4.7 \mu\text{H}$ and 0.106Ω , respectively. The coil impedance was 400Ω at 13.56 MHz. The input power was 90 W, and the reflected power was less than 1 W. The gas flow rate and pressure were 10 sccm and 50-100 mTorr, respectively.

The plasma emission was fiber-optically coupled through a 220F matching fiber adapter positioned 2 cm from the cell wall to a high resolution visible spectrometer with a resolution of $\pm 0.06 \text{ \AA}$ over the spectral range 1900–8600 \AA . The spectrometer was a Jobin Yvon Horiba 1250 M with 2400 grooves/mm ion-etched holographic diffraction grating. The entrance and exit slits were set to $20 \mu\text{m}$. The spectrometer was scanned between 6555–6570 \AA and 4000–7000 \AA using a 0.05 \AA step size. The signal was recorded by a PMT with a stand alone high voltage power supply (950 V) and an acquisition controller. The data was obtained in a single accumulation with a 1 second integration time.

The method of Videnovic *et al.* [21] was used to calculate the energetic hydrogen atom densities and energies from the width of the 6562.8 \AA Balmer α line emitted from hydrogen and water microwave plasmas. The full half-width $\Delta\lambda_G$ of each Gaussian results from the Doppler ($\Delta\lambda_D$) and instrumental ($\Delta\lambda_I$) half-widths:

$$\Delta\lambda_G = \sqrt{\Delta\lambda_D^2 + \Delta\lambda_I^2} \quad (1)$$

$\Delta\lambda_I$ in our experiments was 0.06 \AA . The temperature was calculated from the Doppler half-width using the formula:

$$\Delta\lambda_D = 7.16 \times 10^{-6} \lambda_0 \left(\frac{T}{\mu} \right)^{1/2} (\text{\AA}) \quad (2)$$

where λ_0 is the line wavelength in \AA , T is the temperature in K ($1 \text{ eV} = 11,605 \text{ K}$), and μ is the molecular weight (=1 for hydrogen). In each case, the average Doppler half-width that was not

appreciably changed with pressure varied by $\pm 5\%$ corresponding to an error in the energy of $\pm 5\%$. The corresponding number densities for noble gas-hydrogen mixtures varied by $\pm 20\%$.

To measure the absolute intensity, the high resolution visible spectrometer and detection system were calibrated [22] with 5460.8 Å, 5799.6 Å, and 6965.4 Å light from a Hg-Ar lamp (Ocean Optics, model HG-1) that was calibrated with a NIST certified silicon photodiode. The population density of the $n = 3$ hydrogen excited state N_3 was determined from the absolute intensity of the Balmer α (6562.8 Å) line measured using the calibrated spectrometer. The spectrometer response was determined to be approximately flat in the 4000-7000 Å region by ion etching and with a tungsten intensity calibrated lamp. The absolute intensities of $n = 4$ to 9 were determined from the absolute intensity of Balmer α ($n = 3$) and the relative intensity ratios.

The VUV spectrometer was a normal incidence 0.2 meter monochromator equipped with a 1200 lines/mm holographic grating with a platinum coating that covered the region 20 – 5600 Å. The VUV spectrum was recorded with a CEM. The wavelength resolution was about 0.2 Å (FWHM) with slit widths of 50 µm. The increment was 2 Å and the dwell time was 500 ms. The VUV spectra (900 – 1300 Å) of the water and control hydrogen plasmas were recorded at 90 W input power.

The spectrometer was calibrated between 400-2000 Å with a standard discharge light source using He, Ne, Ar, Kr, and Xe lines: He I (584 Å), He II (304 Å), Ne I (735 Å), Ne II (460.7 Å), Ar I (1048 Å), Ar II (932 Å), Kr II (964 Å), Xe I (1295.6 Å), Xe II (1041.3 Å), Xe II (1100.43 Å). The wavelength and intensity ratios matched those given by NIST [23]. The spectrometer response was determined to be approximately flat in the 1000-1300 Å region. The calculation of the number density of the $n = 3$ to 9 states was corrected for the minor variation of the sensitivity with wavelength in this region.

The electron density and temperature of the rt-plasma was determined using a compensated Langmuir probe according to the method given previously [24].

III. RESULTS AND DISCUSSION

A. Hydrogen Balmer and Lyman series emission

The high resolution visible spectra (4000–6700 Å) of the cell emission from a hydrogen microwave plasma with 90 W input power, a water microwave plasma with 50 W input power, and a water microwave plasma with 90 W input power are shown in Fig. 2–4, respectively. As shown by the absolute intensity measurements of the Balmer lines of the hydrogen microwave plasma, we observed the known ratios of the Balmer lines. In contrast, the population of the levels $n = 4$, $n = 5$, and $n = 6$ of hydrogen were continuously inverted with respect to $n = 3$ in the water plasma spectrum shown in Fig. 3. The relative intensities of the Balmer lines of microwave plasmas of hydrogen (90-2%) mixed with xenon, krypton, or nitrogen at 50 W were equivalent those of hydrogen alone; thus, the inversion is not inherent to a hydrogen plasma generated by microwaves. As shown in Fig. 4, when the input power was increased to 90 W, the $n = 5$ and $n = 6$ levels were further continuously inverted with respect to $n = 4$. The levels $n = 7$, $n = 8$, and $n = 9$ of hydrogen were also continuously inverted with respect to $n = 3$. Thus, wavelength tunability may be achieved by varying the microwave power with lasing between the corresponding power-dependent inverted levels. The requirement for a stoichiometric mixture was fairly exacting since it was observed that additions of increasing partial pressures of pure hydrogen or oxygen progressively reversed the inversion at a mole fraction over the stoichiometric ratio of greater than 2%.

The VUV spectra (900 – 1300 Å) of the cell emission from hydrogen microwave and the water microwave plasmas with 90 W input power are shown in Fig. 5. An inverted Lyman population was also observed from the water plasma emission with the inversion observed in the visible as shown in Fig. 2 extending to the $n = 2$ level. No inversion was observed for the hydrogen microwave plasma.

No inversion was observed with inductively or capacitively RF driven or high voltage glow discharge water plasmas as shown in Fig. 6–8, respectively. However, intense emission of OH⁺ radicals in water plasmas was observed from glow discharge as well as microwave sources as shown in Fig. 8 and 4, respectively. As discussed previously, the glow discharge plasma has been extensively studied as a light source based on the emission of OH⁺ radicals [15]. Shuaibov *et al.* [25] give the spectrum of a glow discharge of a He/H₂O mixture and assign the OH($A - X$) emission. As a comparison, the OH($A - X$) microwave water plasma emission spectrum in the region of 2800–3300 Å is given in Fig. 9. The (1-0) R-branch and the (1-0) Q-branch are observed in the 2800–2950 Å region as shown in Fig. 10. The (0-0) R-branch and the (0-0), (1-1), and (2-2) Q-branches are observed in the 3000–3300 Å region as shown in Fig. 11.

We had shown previously that the conditions of the particular discharge may be a major parameter in the observation of excessive Doppler Balmer line broadening with plasmas of hydrogen and a noble ion having an ionization potential of an integer multiple of E_h [8–11, 16–18]. We proposed that the corresponding energetic hydrogen formed with an Evenson microwave cavity may be a means to achieve population inversion.

Other explanations of the population inversion were ruled out. The spectrometer response was determined to be approximately flat in the 4000–7000 Å region by ion etching and with an intensity calibrated lamp. Furthermore, the Balmer and Lyman line intensity ratios of the

control hydrogen plasmas closely matched those obtained using the NIST Einstein A coefficients [23]. Since these ratios did not change as the pressure was lowered, and the hydrogen pressure was lower in the water plasma than the control, the NIST Einstein A coefficients were used to calculate the number density ratios from the water plasma emission.

To investigate whether the water plasmas of this study were optically thin or thick at a given frequency ω , the effective path length $\tau_\omega(L)$ was calculated from

$$\tau_\omega(L) = \kappa_\omega L \quad (3)$$

where L is the path length and κ_ω is the absorption coefficient given by

$$\kappa_\omega = \sigma_\omega X N_H \quad (4)$$

where σ_ω is the absorption cross section and N_H is the number density of the absorber. For optically thin plasmas $\tau_\omega(L) < 1$, and for optically thick plasmas $\tau_\omega(L) > 1$. By orders of magnitude, self absorption of Lyman emission by $n = 1$ state hydrogen dominates since $n = 1$ H dominates the H population distribution. At 1215.67 Å, the effective path length $\tau_\omega(5\text{ cm})$ was calculated from Eq. (3) using the absorption cross section for Lyman α emission, $\sigma = 4 \times 10^{-16} \text{ cm}^2$ [26], and $N_H = 6 \times 10^{13} \text{ cm}^{-3}$.

$$\tau_\omega(5\text{ cm}) = \kappa_\omega L = (4 \times 10^{-16} \text{ cm}^2)(6 \times 10^{13} \text{ cm}^{-3})(5\text{ cm}) = 1 \times 10^{-1} \quad (5)$$

Since $\tau_\omega(5) \ll 1$, the water plasmas were optically thin. Furthermore, the water plasmas were determined to be optically thin for hydrogen absorption of the Balmer and as well as the additional Lyman lines. Thus, absorption of 6562.8 Å and 4861.3 Å and 1215.67 Å emission by $n = 2$ and $n = 1$ state atomic hydrogen, respectively, may be neglected as the cause of the inverted ratios.

The absorption cross section of Balmer emission by water is insignificant—nine orders of magnitude less than in the Lyman region [27]. Thus, the Balmer lines were used to determine the

over populations in Table 1, except for the $n = 2$ level which was determined from the intensities of the Lyman lines. The effective path length $\tau_\omega(5 \text{ cm})$ was calculated from Eq. (3) using the absorption cross section of water for Lyman α emission, $\sigma = 1.6 \times 10^{-17} \text{ cm}^2$ [28], and the water number density, $N_{\text{H}_2\text{O}} = 2.5 \times 10^{15} \text{ cm}^{-3}$, calculated from the measured pressure.

$$\tau_\omega(5 \text{ cm}) = \kappa_\omega L = (1.6 \times 10^{-17} \text{ cm}^2)(2.5 \times 10^{15} \text{ cm}^{-3})(5 \text{ cm}) = 0.2 \quad (6)$$

Since $\tau_\omega(5) < 1$, the water plasmas were optically thin.

B. Measurement of hydrogen atom temperature and number density from Balmer line broadening

To further characterize the water plasma, the width of the 6562.8 \AA Balmer α line ($n = 3$ to $n = 2$) was measured on light emitted from the microwave discharges of pure hydrogen alone and water vapor maintained under equivalent conditions using the high resolution visible spectrometer as shown in Fig. 12 and 13, respectively. The method of Videnovic *et al.* [21] was used to calculate the hydrogen atom energies and densities from the line width. Significant line broadening of 55 eV and an atom density of $6 \times 10^{13} \text{ atoms/cm}^3$ was observed from the water plasma compared to an average hydrogen atom temperature of 1 eV and a density of $6 \times 10^{11} \text{ atoms/cm}^3$ for hydrogen alone. Similarly, using a Langmuir probe as described previously [24], the electron temperature T_e measured on the microwave water plasmas was higher, 2.0 eV, compared to the $T_e \leq 1 \text{ eV}$ measured on the hydrogen plasma at the same 50 W input power.

We have assumed that Doppler broadening due to thermal motion was the dominant source in the water plasmas to the extent that other sources may be neglected. To confirm this

assumption, each source is now considered. In general, the experimental profile is a convolution of two Doppler profiles, an instrumental profile, the natural (lifetime) profile, Stark profiles, van der Waal's profiles, a resonance profile, and fine structure. The instrumental half-width is measured to be ± 0.06 Å. The natural half-width of the Balmer α line given by Djurovic and Roberts [29] is 1.4×10^{-3} Å which is negligible. The fine structure splitting is also negligible.

Stark broadening of hydrogen lines in plasmas can not be measured at low electron densities using conventional emission or absorption spectroscopy because it is hidden by Doppler broadening. In the case of the Lyman α line, the Stark width exceeds the Doppler width only at $n_e > 10^{17}$ cm $^{-3}$ for temperatures of about 10 4 K [30].

The relationship between the Stark broadening $\Delta\lambda_s$ of the Balmer β line in nm, the electron density n_e in m $^{-3}$, and the electron temperature T_e in K is

$$\log n_e = C_0 + C_1 \log(\Delta\lambda_s) + C_2 [\log(\Delta\lambda_s)]^2 + C_3 \log(T_e) \quad (7)$$

where $C_0 = 22.578$, $C_1 = 1.478$, $C_2 = -0.144$, and $C_3 = 0.1265$ [31]. From Eq. (7), to get a Stark broadening of only 1 Å with $T_e = 9000$ K, an electron density of about $n_e \sim 3 \times 10^{15}$ cm $^{-3}$ is required compared to that of the water plasma of $n_e = 0.2 \times 10^8$ cm $^{-3}$ determined using a Langmuir probe, over seven orders of magnitude less. Gigosos and Cardenoso [32] give the observed Balmer α Stark broadening for plasmas of hydrogen with helium or argon as a function of the electron temperature and density. For example, the Stark broadening of the Balmer α line recorded on a H + He $^+$ plasma is only 0.33 Å with $T_e = 20,000$ K and $n_e = 1.4 \times 10^{14}$ cm $^{-3}$. Thus, the Stark broadening was also insignificant.

The statistical curve fit of the hydrogen and water microwave plasma emission are shown in Fig. 12 and 13, respectively. In each case, the data matched a Gaussian profile having the X 2

and R^2 values given in Fig. 12 and 13. The absence of Stark broadening in the water plasma is also evident by the good fit to a Gaussian profile rather than a Voigt profile as shown in Fig. 13.

A linear Stark effect arises from an applied electric field that splits the energy level with principal quantum number n into $(2n - 1)$ equidistant sublevels. The magnitude of this effect given by Videnovic *et al.* [21] is about 2×10^{-2} nm/kV·cm⁻¹. No applied electric field was present in our study; thus, the linear Stark effect should be negligible.

The plasma was evaluated for optical thickness. The absorption cross section for Balmer α emission is $\sigma = 1 \times 10^{-16}$ cm² [26]. As discussed *infra.*, an estimate based on Lyman line intensity, the $n = 2$ H atom density is $\sim 1.39 \times 10^9$ cm⁻³. Thus, for a plasma length of 5 cm, the effective path length, $\tau_\omega(5\text{ cm})$, calculated from Eq. (3) for Balmer α is

$$\tau_\omega(5\text{ cm}) = \kappa_\omega L = (1 \times 10^{-16} \text{ cm}^2)(1.39 \times 10^9 \text{ cm}^{-3})(5 \text{ cm}) = 6.95 \times 10^{-7} \quad (8)$$

Since $\tau_\omega(5) \ll 1$, the water plasmas were optically thin; so, the self absorption of 6562.8 Å emission by $n = 2$ state atomic hydrogen may be neglected as a source of the observed broadening.

As discussed above, an estimate based on emission line profiles places the total H atom density of the water plasma at $\sim 6 \times 10^{13}$ cm⁻³. Since this is overwhelmingly dominated by the ground state, $N_H = 6 \times 10^{13}$ cm⁻³ will be used. Usually, the atomic hydrogen collisional cross section in plasmas is on the order of 10^{-18} cm² [33]. Thus, for $N_H = 6 \times 10^{13}$ cm⁻³, collisional or pressure broadening is negligible.

Prior studies that reported fast H, attributed the observation to acceleration of ions in a high electric fields at the cathode fall region and an external field Stark effect [21, 34, 35]. Observations with a microwave plasma having no high field present was reported previously

[16–18]. Microwave helium-hydrogen and argon-hydrogen plasmas showed extraordinary broadening corresponding to an average hydrogen atom temperature of 180–210 eV and 110–130 eV, respectively. Whereas, pure hydrogen and xenon-hydrogen microwave plasmas showed no excessive broadening corresponding to an average hydrogen atom temperature of ≈ 4 eV [16–18]. The formation of fast H was explained by a resonance energy transfer between hydrogen atoms and Ar^+ or He^+ of an integer multiple of the potential energy of atomic hydrogen, 27.2 eV.

As in the case of the argon-hydrogen or helium-hydrogen plasmas, no hydrogen species, H^+ , H_2^+ , H_3^+ , H^- , H, or H_2 , of the water plasmas responds to the microwave field; rather, only the electrons respond. However, the measured electron temperature in these microwave plasmas was about 1–2 eV; whereas, the measured neutral hydrogen temperature was much higher, 55 eV. This requires that $T_i \gg T_e$ which can not be due to direct ion coupling to the microwave power or electron-collisional excitation. Nor, can this result be explained by electric field acceleration of charged species as proposed for glow discharges [21, 34, 35] since in microwave driven plasmas, there is no high electric field in a cathode fall region (> 1 kV/cm) to accelerate positive ions. The observation of excessive Balmer line broadening in a microwave driven plasma requires a source of energy. In the case of the water plasma, we propose that the source is the energy is due to a resonant energy transfer between hydrogen atoms and oxygen. The catalysis mechanism was supported by the observation of O^{2+} at 3715.0 Å, 3754.8 Å, and 3791.28 Å as shown in Fig. 14 as well as the extraordinary line broadening Balmer line broadening of 55 eV compared to 1 eV for hydrogen alone. This energy may be the basis of the pumping source for the observed population inversions.

Then the inverted population is explained by a resonance energy transfer between hydrogen and oxygen to yield fast $H(n=1)$ atoms. The emission of excited state H from fast $H(n=1)$ atoms excited by collisions with the background H_2 has been discussed by Radovanov *et al.* [35]. Formation of H^+ is also predicted by a collisional radiative model [11] which is far from thermal equilibrium in terms of the hydrogen atom temperature. Akatsuka *et al.* [6] show that it is characteristic of cold recombining plasmas to have the high lying levels in local thermodynamic equilibrium (LTE); whereas, for the low lying levels, population inversion is obtained when T_e becomes low with an appropriate electron density as shown by the Saha-Boltzmann equation.

C. Level population and lasing ability

To determine the potential of the water-plasma as a laser medium, the absolute reduced Balmer population density of the excited hydrogen atoms $\frac{N_n}{g_n}$ with principal quantum numbers $n = 1$ to 9 were obtained from N , their absolute intensity integrated over the visible spectral peaks shown in Fig. 3 and 4 corrected by their Einstein coefficients, divided by g , the statistical weight ($g = 2n^2$), as discussed by Akatsuka *et al.* [6]. As given in Table 1, $\frac{N_n}{g_n}$ for quantum number $n = 3, 4, 5, 6$ recorded on a water microwave plasma at 90 W input was determined to be $3.44 \times 10^8 \text{ cm}^{-3}$, $3.44 \times 10^8 \text{ cm}^{-3}$, $9.02 \times 10^8 \text{ cm}^{-3}$, and $385 \times 10^8 \text{ cm}^{-3}$, respectively.

The population of the $n = 2$ level was determined from the VUV spectrum (900 – 1300 Å) of the microwave water plasma shown in Fig. 5. From the number densities of the levels determined from the absolute Balmer line intensities given in Table 1 and the Lyman lines intensities shown in Fig. 5, it was found that

$$\frac{N_4}{N_3} \text{ Balmer} = 4.66; \frac{N_4}{N_3} \text{ Lyman} = 4.46 \quad (9)$$

Since $\frac{N_4}{N_3}$ determined from the Lyman series and the Balmer series was about the same, and the Balmer α line was absolutely measured, the absolute number density for $n = 2$ given in Table 1 was determined from the absolute Balmer α line intensity.

$$(N_2)_{\text{Balmer}} = (N_3)_{\text{Balmer}} \times \left(\frac{(N_2)_{\text{Lyman}}}{(N_3)_{\text{Lyman}}} \right) \quad (10)$$

Using $N_3 = 6.20 \times 10^9 \text{ cm}^{-3}$ and $g_2 = 8$, $\frac{N_2}{g_2}$ was determined to be $1.74 \times 10^8 \text{ cm}^{-3}$.

With appropriate cavity length and mirror reflection coefficient, cw laser oscillations may be obtained between states having an overpopulation ratio determined by $\frac{N_i}{N_f} \frac{g_f}{g_i} > 1$ as shown in Table 1 where i represents the quantum number of the initial state and f represents that of the final state [6]. On this basis, it was determined that lasing is possible over a wide range from far infrared to violet wavelengths. Representative transitions and wavelengths are shown in Table 2. The important parameter for lasing is that the reduced overpopulation density is above threshold. Using standard laser cavity equations [6], it was determined that the threshold condition is achievable with micron to submillimeter laser cavities for several transitions emitted from these plasmas. For plasma properties of this experiment determined using a Langmuir probe ($T_e = 2.0 \text{ eV}$, electron density $n_e = 0.2 \times 10^8 \text{ cm}^{-3}$), conditions for lasing at $12,818.1 \text{ \AA}$, 4340.5 \AA , and 4101.7 \AA corresponding to the transitions $5 \rightarrow 3$, $5 \rightarrow 2$, and $6 \rightarrow 2$, respectively, were determined assuming a cavity length of 100 cm and a combined mirror reflection coefficient of 0.99, as given in Table 3. The overpopulation ratios $\frac{N_5}{N_3} \frac{g_3}{g_5}$, $\frac{N_5}{N_2} \frac{g_2}{g_5}$, and $\frac{N_6}{N_2} \frac{g_2}{g_6}$ given in Table 1

were 112, 221, and 67, respectively. Threshold reduced $n = 5$ overpopulation densities of about $0.49 \times 10^7 \text{ cm}^{-3}$ and $4.6 \times 10^7 \text{ cm}^{-3}$ are required for lasing to $n = 3$ and $n = 2$, respectively, and, a corresponding threshold reduced $n = 6$ overpopulation density of $6.9 \times 10^7 \text{ cm}^{-3}$ is required for lasing to $n = 2$. The actual reduced overpopulation densities were much greater, $3.8 \times 10^{10} \text{ cm}^{-3}$, $3.8 \times 10^{10} \text{ cm}^{-3}$, and $1.2 \times 10^{10} \text{ cm}^{-3}$, respectively. Thus, lasing is expected with cavity lengths of 0.01 cm, 0.2 cm, and 0.6 cm, respectively.

D. Blue and infrared laser applications

A micro-water laser may be possible using proven approaches. As an advancement to the liquid based predecessor, micro-organic dye lasers have been developed by suspending each dye molecule in a cavity of a zeolite rather than in solution [36]. If they can be electrically pumped, such devices may eventually be competitive with semiconductor diode lasers; however, currently they require optical pumping. Microwaves are transparent to materials comprised of silicon or aluminum oxides. Thus, microcavities containing water vapor could potentially provide more competitive alternative microlasers for microelectronics applications that do not suffer from lattice constant and thermal expansion coefficient incompatibilities or require sophisticated materials or structures such as multiple quantum wells [37, 38].

Lasing is possible at blue wavelengths which are ideal for many communications and microelectronics applications as well as at a wavelength of $1.3 \mu\text{m}$ which is ideal for transmission through glass optical fibers. The emission wavelength of the potential water laser is about 400 nm which is suitable for the next generation 15-Gbyte DVDs [1]. Currently, the ideal laser diode for telecommunications applications is the $\text{In}_x\text{Ga}_{1-x}\text{As}_y\text{P}_{1-y}$ diode laser wherein a lattice constant mismatch requires that the laser be separate from the silicon circuits. An

integrated laser would revolutionize telecommunications, electronics, and computing [39]. Conceptually, we see no obvious impediment to integration of a water-plasma laser. In addition, many more laser wavelengths corresponding to Balmer, Paschen, and Brackett lines are possible. With the capability of lasing over the widest range of atomic wavelengths of any known atomic laser, far infrared to violet, the hydrogen laser based on water-plasma may prove to be the most versatile laser yet discovered.

IV. CONCLUSION

The reactions O_2 to O and O^{2+} , O_2 to O and O^{3+} , and $2O$ to $2O^+$ provide a net enthalpy of an integer multiple of the potential energy of atomic hydrogen of 2, 4, and 1 times 27.2 eV, respectively. Stationary inverted H Balmer and Lyman populations were observed from a low pressure water-vapor microwave discharge plasmas. The ionization and population of excited atomic hydrogen levels was attributed to energy provided by the catalytic resonance energy transfer between hydrogen atoms and molecular oxygen formed in the water plasma. The catalysis mechanism was supported by the observation of O^{2+} and H Balmer line broadening of 55 eV compared to 1 eV for hydrogen alone. The catalysis reaction, and consequently the inversion, depended on specific plasma conditions provided by the Evenson microwave cavity. In contrast, no inversion was observed using RF or glow discharge cells. In addition, the requirement for the natural hydrogen-oxygen stoichiometry of the water plasma was stringent in that a deviation by over 2% excess of either gas caused a reversal of the inversion.

The high hydrogen atom temperature with a relatively low electron temperature, $T_e = 2$ eV, due to the catalysis reaction were characteristic of cold recombining plasmas. These conditions of a water plasma favored an inverted population in the lower levels. Thus, the

catalysis of atomic hydrogen may pump a cw HI laser with expected laser oscillations from (i) $n = 3$, $n = 4$, $n = 5$, $n = 6$, $n = 7$ and $n = 8$ to $n = 2$, (ii) $n = 4$, $n = 5$, $n = 6$, and $n = 7$ to $n = 3$ and (iii) $n = 5$ and $n = 6$ to $n = 4$. A micro-water laser capable of integration may be possible using proven approaches. Many more laser wavelengths corresponding to Balmer, Paschen, and Brackett lines are possible. With the capability of lasing over the widest range of atomic wavelengths of any known atomic laser, far infrared to violet, the hydrogen laser based on water-plasma may prove to be the most versatile laser yet discovered.

FIG. 1. The experimental set comprising a quartz tube cell, a source of water vapor, a flow system, and a visible spectrometer.

FIG. 2. The visible spectrum (4000-6700 Å) of the cell emission from a hydrogen microwave plasma at 90 W input power. No inversion was observed.

FIG. 3. The visible spectrum (4000-6700 Å) of the cell emission from a water microwave plasma with 50 W input power. A stationary inverted H Balmer population was observed. The population of the levels $n = 4, 5$, and 6 of hydrogen were continuously inverted with respect to $n = 3$.

FIG. 4. The visible spectrum (2750-7200 Å) of the cell emission from a water microwave plasma with 90 W input power. A stationary inverted H Balmer population was observed. In addition to the continuous population inversion of the H levels $n = 4, 5$, and 6 with respect to $n = 3$ observed at 50 W, the $n = 5$ and 6 levels were further continuously inverted with respect to $n = 4$ when the input power was increased to 90 W. The levels $n = 7, 8$, and 9 of hydrogen were also continuously inverted with respect to $n = 3$.

FIG. 5. The VUV spectra (900-1300 Å) of the cell emission from hydrogen microwave and water microwave plasmas with 90 W input power. An inverted Lyman population was observed from the water plasma emission with the inversion observed in the visible as shown in Fig. 3 and Fig. 4 extending to the $n = 2$ level.

FIG. 6. The visible spectrum (3000-7200 Å) of the cell emission from an inductively coupled water RF plasma with 90 W input power. No inversion was observed.

FIG. 7. The visible spectrum (3000-7200 Å) of the cell emission from a capacitively coupled water RF plasma with 90 W input power. No inversion was observed.

FIG. 8. The visible spectrum (2750-7200 Å) of the cell emission from a water high voltage glow discharge plasma with 90 W input power. Strong $OH(A - X)$ emission, but no inversion was observed.

FIG. 9. The $OH(A - X)$ microwave water plasma emission spectrum in the region of 2750-3300 Å with 90 W input power.

FIG. 10. The $OH(A - X)$ (1-0) R-branch and the (1-0) Q-branch were observed in the 2800-2950 Å region of the microwave water plasma emission spectrum shown in Fig. 9.

FIG. 11. The $OH(A - X)$ (0-0) R-branch and the (0-0), (1-1), and (2-2) Q-branches were observed in the 3000-3300 Å region of the microwave water plasma emission spectrum shown in Fig. 9.

FIG. 12. The 6562.8 Å Balmer α line width recorded with a high resolution (± 0.06 Å) visible spectrometer on a hydrogen microwave discharge plasma. The statistical curve fit of

the Balmer α line width profile matched a Gaussian profile having the $X^2 = \sum \frac{(\text{Calculated} - \text{Measured})^2}{\text{Calculated}}$ and R^2 (correlation coefficient squared) values of 4.86 and 0.99, respectively. No line excessive broadening was observed corresponding to an average hydrogen atom temperature of 1 eV.

FIG. 13. The 6562.8 Å Balmer α line width recorded with a high resolution (± 0.06 Å) visible spectrometer on a water vapor microwave discharge plasma. The statistical curve fit of the Balmer α line width profile matched a Gaussian profile having the X^2 and R^2 values of 7.48 and 0.996, respectively. Significant broadening was observed corresponding to an average hydrogen atom temperature of 55 eV.

FIG. 14. The visible spectrum (3700-3960 Å) of the cell emission from a water microwave plasma with 90 W input power. The catalysis mechanism was supported by the observation of O^{2+} at 3715.0 Å, 3754.8 Å, and 3791.28 Å. O^+ was observed at 3727.2 Å, 3749.4 Å, 3771 , 3872 Å, and 3946.3 Å. The hydrogen Balmer lines corresponding to the transitions 10-2, 9-2, and 8-2 were also observed.
